8. Statement-Level Control Structures
   • selection statements
     o if
     o case
   • iterative
     o while
     o repeat – until
     o for
   • unconditional branching
     o goto
   • guarded command control structures
     o Dijkstra

8.1. Introduction
• while and if are sufficient – Bohm and Jacopini 1966

8.2. Selection Statements
• A selection statement provides the means of choosing between two or more execution paths in a program.

8.2.1. Two-Way Selection Statements
• One-armed if
  \[ \text{if control-expression then-clause} \]

• Two-armed if
  \[ \text{if control-expression then-clause else-clause} \]

8.2.1.1. Design Issues
• What is the form and type of the expression that controls the selection?
• How are the then and else clauses specified?
• How should the meaning of nested selectors be specified?

8.2.1.2. The Control Expression
• Syntactic markers are required to distinguish the control-expression. One of two alternatives are generally chosen as exemplified by Pascal and C++.
  o Pascal
    if control-expression then then-clause
    if i<0 then i=-i; {one-armed if}
    if control-expression then then-clause else else-clause
    if (p>0) and (p>q) {two-armed if}
      then begin p:=p-q; q:=p+q end
      else begin p:=p+q; q:=p-q end;

  o C++
    if (control-expression) then-clause
    if i<0 i=-i; //one-armed if
    if (control-expression) then-clause else else-clause
    if (p>0 && p>q) { //two-armed if
      p:=p-q; q:=p+q;
    } else {
      p:=p+q; q:=p-q;
    }

  o Ada
    if i<0 then i=-i; end if; --one-armed if
    if p>0 and p>q --two-armed if
      then p:=p-q; q:=p+q;
      else begin p:=p+q; q:=p-q;
    end if;

  o Ruby
    if sum==0 then
      if count==0 then
        result=0
      else
        result=1
      end
    end

8.2.1.3. Clause Form
• Issue: single or compound statement
• Perl – all then and else clauses must be compound statements
• C-Based languages, JavaScript, Perl enclose compound statements in curly braces.
• Fortran 95, Ada, Python, and Ruby – then and else clauses are statement sequences. The complete selection construct is terminated with a reserve word.
• Python uses indentation to specify compound statements. For example, if x>y :
  x = y
  print “case 1”
8.2.1.4. Nesting Selectors

- Issue: which if-statement does an else-clause belong to when it is nested?
  
  ```
  if (sum==0)
    if (count==0)
      result=0;
    else //Does this else belong to if (sum==0)
      result=1; //Or does this else belong to if (count==0)
  ```

- Normally, the static semantics of the language specify that the else-clause is always paired with the nearest previous unpaired then-clause.
- Compound-statements can force the issue
  
  ```
  if (sum==0) {
    if (count==0) result=0;
  } else result=1;
  ```

8.2.2. Multiple-Selection Statements

- The multiple-selection construct allows the selection of one of any number of statements or statement groups.

8.2.2.1. Design Issues

- What is the form and type of the expression that controls the selection?
- How are the selectable segments specified?
- Is execution flow through the structure restricted to include just a single selectable segment?
- How are the case values specified?
- How should unrepresented selector expression values be handled, if at all?

8.2.2.2. Examples of Multiple Selectors

- C, C++, Java
  
  ```
  switch (index) {
    case 1:
    case 3: odd+=1;
      sumodd+=index;
      break;
    case 2:
    case 4: even+=1;
      sumeven+=index;
      break;
    default: cout << “Error in switch, index = “ << index;
  }
  ```

Notes:

1. Without the break-statement control continues to the next alternative.
• C#
  
```c#
switch (value) {
  case -1:
    Negatives++;
    break;
  case 0:
    Zeros++;
    goto case 1;
  case 1:
    Positives++;
    break;
  default:
    Console.WriteLine("Error in switch 
");
    break;
}
```

Notes:
1. Every selectable segment must end with an explicit unconditional branch statement: either a `break`, which transfers control out of the switch construct, or a `goto`, which can transfer control to one of the selectable segments (or virtually anywhere else).

• Pascal
  
```pascal
type direction=(North,East,South,West);
var x:direction;
...
  case x of
    North: x:=East;
    East: x:=South;
    South: x:=West;
    West: x:=North
end;
```

• Ada
  
```ada
case x of
  when North => x:=East;
  when East  => x:=South;
  when South => x:=West;
  when West  => x:=North;
end;
```

• Ruby
  
```ruby
case when Boolean-expression then expression
...
when Boolean-expression then expression
[else expression]
end
```
8.2.2.3. Implementing Multiple Selection Structures

- A multiple selection construct is essentially an $n$-way branch to segments of code, where $n$ is the number of selectable segments.
- Implementing such a construct must be done with multiple conditional branch instructions.

//The following code fragment in C++ is implemented below
switch (expression) {
    case constant-expression-1: statement-1;
    break;
    ...
    case constant-expression-n: statement-n;
    break;
    [default: statement-n+1]
}

//The foregoing code fragment in C++ is implemented below
t = expression;
goto branches
label-1: code for statement-1
goto out;
...
label-n: code for statement-n
goto out;
default: code for statement-n+1
goto out;

branches: if $t==$constant-expression-1 goto label-1
    ...
    if $t==$constant-expressionn-n goto label-n
goto default

go to out:
8.2.2.4. Multiple Selection Using if

- Python
  
  ```
  if count < 10 :
    bag1=True
  elif count < 100 :
    bag2=True
  elif count < 1000 :
    bag3=True
  else :
    bag4=True
  ```

  Implemented as

  ```
  if count < 10 :
    bag1=True
  else :
    if count < 100 :
      bag2=True
    else :
      if count <1000 :
        bag3=True
      else :
        bag4=True
  ```

8.3. Iterative Statements

- The repeated execution of a statement or compound statement is accomplished either by iteration or recursion.
- General design issues for iteration control statements:
  - How is iteration controlled?
  - Where is the control mechanism in the loop?
  - Entrances and exits

8.3.1. Counter-Controlled Loops

- A counting iterative statement has a loop variable, and a means of specifying the initial and terminal, and stepsize values.

8.3.1.1. Design Issues

  - What are the type and scope of the loop variable?
  - Should it be legal for the loop variable or loop parameters to be changed in the loop body, and if so, does the change affect loop control?
  - Should the loop parameters be evaluated only once, or once for every iteration?
8.3.1.2. The Do Statements of Fortran 95

- FORTRAN 95 syntax
  DO label var = start, finish [, stepsize]
- Step size can be any value but zero
- Parameters can be expressions
- Design choices:
  - Loop variable must be INTEGER
  - The loop variable cannot be changed in the loop, but the parameters can; because they are evaluated only once, it does not affect loop control
  - Loop parameters are evaluated only once
  - FORTRAN 95: a second form:
    [name:] Do variable = initial, terminal [,stepsize]
    ...
End Do [name]
- Cannot branch into either of Fortran’s Do statements

8.3.1.3. The Ada For Statement

- Ada
  for var in [reverse] discrete_range loop               ...
  end loop
- Design choices:
  - Type of the loop variable is that of the discrete range (A discrete range is a sub-range of an integer or enumeration type).
  - Loop variable does not exist outside the loop
  - The loop variable cannot be changed in the loop, but the discrete range can; it does not affect loop control
  - The discrete range is evaluated just once
- Cannot branch into the loop body

8.3.1.4. The For Statement of the C-Based Language

- C-based languages
  for ([expr_1] ; [expr_2] ; [expr_3]) statement
  - The expressions can be whole statements, or even statement sequences, with the statements separated by commas
  - The value of a multiple-statement expression is the value of the last statement in the expression
  - If the second expression is absent, it is an infinite loop
- Design choices:
  - There is no explicit loop variable
  - Everything can be changed in the loop
The first expression is evaluated once, but the other two are evaluated with each iteration

- C++ differs from C in two ways:
  1. The control expression can also be Boolean
  2. The initial expression can include variable definitions (scope is from the definition to the end of the loop body)

- Java and C#:
  1. Differs from C++ in that the control expression must be Boolean

8.3.1.5. The For Statement of Python

- Python
  
  ```python
  for loop_variable in object:
    - loop body
  [else:
    - else clause]
  ```
  
  - The object is often a range, which is either a list of values in brackets ([2, 4, 6]), or a call to the range function (range(5), which returns 0, 1, 2, 3, 4)
  - The loop variable takes on the values specified in the given range, one for each iteration
  - The else clause, which is optional, is executed if the loop terminates normally

8.3.2. Logically Controlled Loops

- Repetition control is based on a Boolean expression

8.3.2.1. Design Issues

- Pretest or posttest?
- Should the logically controlled loop be a special case of the counting loop statement or a separate statement?

8.3.2.2. Example

- C and C++ have both pretest and posttest forms, in which the control expression can be arithmetic:
  
  ```
  while (ctrl_expr) do
    loop body
  loop body
  while (ctrl_expr)
  ```

- Java is like C and C++, except the control expression must be Boolean (and the body can only be entered at the beginning -- Java has no goto
- Ada has a pretest version, but no posttest
• FORTRAN 95 has neither
• Perl and Ruby have two pretest logical loops, while and until. Perl also has two posttest loops

8.3.3. User-Located Loop Control Mechanisms

• Sometimes it is convenient for the programmers to decide a location for loop control (other than top or bottom of the loop)
• Simple design for single loops (e.g., break)
• Design issues for nested loops
  1. Should the conditional be part of the exit?
  2. Should control be transferable out of more than one loop?
• C, C++, Python, Ruby, and C# have unconditional unlabeled exits (break)
• Java and Perl have unconditional labeled exits (break in Java, last in Perl)
• C, C++, and Python have an unlabeled control statement, continue, that skips the remainder of the current iteration, but does not exit the loop
• Java and Perl have labeled versions of continue

8.3.4. Iteration Based on Data Structures

• Number of elements of in a data structure control loop iteration
• Control mechanism is a call to an iterator function that returns the next element in some chosen order, if there is one; else loop is terminate
• C's for can be used to build a user-defined iterator:
  ```c
  for (p=root; p==NULL; traverse(p)){
  ```

PHP
- current points at one element of the array
- next moves current to the next element
- reset moves current to the first element
  ```java
  ```
  ```java
  ```
  ```java
  ```
- For any collection that implements the Iterator interface
- next moves the pointer into the collection
- hasNext is a predicate
- remove deletes an element
  ```java
  ```
  ```java
  ```
  ```java
  ```
- For arrays and any other class that implements Iterable interface, e.g., ArrayList
  ```java
  ```
  ```java
  ```
  ```java
  ```
- C#'s foreach statement iterates on the elements of arrays and other collections:
  ```c
  Strings[] = strList = {"Bob", "Carol", "Ted"};
  foreach (Strings name in strList)
  Console.WriteLine ("Name: {0}", name);
  ```
  ```c
  ```
  ```c
  ```
  ```c
  ```
- The notation {0} indicates the position in the string to be displayed
• Lua
  – Lua has two forms of its iterative statement, one like Fortran’s Do, and a more general form:
    ```
    for variable_1 [, variable_2] in iterator(table) do
      ...
    end
    ```
  – The most commonly used iterators are `pairs` and `ipairs`

8.4. Unconditional Branching

• Transfers execution control to a specified place in the program
• Represented one of the most heated debates in 1960’s and 1970’s
• Major concern: Readability
• Some languages do not support goto statement (e.g., Java)
• C# offers goto statement (can be used in switch statements)
• Loop exit statements are restricted and somewhat camouflaged goto’s

8.5. Guarded Commands

• Designed by Dijkstra
• Purpose: to support a new programming methodology that supported verification (correctness) during development
• Basis for two linguistic mechanisms for concurrent programming (in CSP and Ada)
• Basic Idea: if the order of evaluation is not important, the program should not specify one
• Form
  ```
  if <Boolean exp> -> <statement>
  [] <Boolean exp> -> <statement>
  ...:
  [] <Boolean exp> -> <statement>
  fi
  ```
• Semantics: when construct is reached,
  – Evaluate all Boolean expressions
  – If more than one are true, choose one non-deterministically
  – If none are true, it is a runtime error
• Connection between control statements and program verification is intimate
• Verification is impossible with goto statements
• Verification is possible with only selection and logical pretest loops
• Verification is relatively simple with only guarded commands

8.6. Conclusions

• Variety of statement-level structures
• Choice of control statements beyond selection and logical pretest loops is a trade-off between language size and writability
• Functional and logic programming languages are quite different control structures
